The optical absorption spectrum for light with electric field perpendicular to a bilayer graphene is shown to be quite different from that for parallel polarization. This arises partly from the difference in the selection rule and from the important depolarization effect due to induced polarization. The depolarization effect is most prominent for the sharp transition between the lowest to the first excited conduction band, which are almost parallel to each other.

Keywords: graphene, bilayer, two-dimensional graphite, optical transition, depolarization effect, dynamical screening

§1. Introduction

Bilayer graphenes consisting of two layers were recently fabricated and various phenomena started to be investigated. The purpose of this paper is to study optical absorption for light with electric field perpendicular to the layer and to clarify the difference from that for light incident normal to the layer.

In an effective-mass approximation, an electron in a monolayer graphene is described by Weyl's equation for a massless neutrino. Transport properties in such an exotic system are intriguing and the conductivity with/without magnetic field including the Hall effect, dynamical transport, and quantum corrections to the conductivity were theoretically investigated. The system was shown to exhibit various properties different from conventional two-dimensional systems.

A bilayer graphene has electronic states quite different from those in the monolayer system as was studied for the band structure with or without a magnetic field, and dynamical properties, and diamagnetic susceptibility. One important feature is that the band structure can be strongly modified due to opening-up of a gap by applied electric field.

The paper is organized as follows: In §2, the dynamical conductivity describing optical transitions is introduced and some of its properties are discussed for a symmetric bilayer. Explicit numerical results in bilayers with asymmetric potential self-consistently determined are presented in §3. Results are discussed and a short summary is presented in §4.

§2. Formulation

2.1 Effective-mass description

We consider a bilayer graphene which is arranged in the AB (Bernal) stacking. The upper layer is denoted as 1 and the lower layer denoted as 2. In a monolayer graphene the conduction and valence bands consisting of π orbitals cross at K and K’ points of the Brillouin zone, where the Fermi level is located. Electron states near a K point are described by the k·p equation equivalent to Weyl’s equation or a Dirac equation with vanishing rest mass. For the inter-layer coupling, we include only the coupling between vertically neighboring atoms. Then, electronic states are described by the k·p equation:

\[ \mathcal{H}_0 \hat{F}(r) = \varepsilon \hat{F}(r), \]  

with

\[ \mathcal{H}_0 = \begin{pmatrix} eFd/2 & \gamma \hat{k}_- & 0 & 0 \\ \gamma \hat{k}_+ & eFd/2 & \Delta & 0 \\ 0 & \Delta & -eFd/2 & \gamma \hat{k}_- \\ 0 & 0 & \gamma \hat{k}_+ & -eFd/2 \end{pmatrix}, \]

and

\[ \hat{k}_\pm = \hat{k}_x \pm i\hat{k}_y, \]

where \( \gamma \) is a band parameter, \( \hat{k} = (\hat{k}_x, \hat{k}_y) = -i\nabla \) is a wave-vector operator, \( \Delta \) represents the inter-layer coupling, and \( eFd \) represents the potential difference between layers 1 and 2 (\( F \) is the effective electric field and \( d = 3.34 \, \text{Å} \) is the interlayer distance), as illustrated in Fig. 1 (a).

Parameters \( \gamma \) and \( \Delta \) are related to tight-binding parameters \( \gamma_0 \) and \( \gamma_1 \) through \( \gamma = (\sqrt{3}/2)\alpha \gamma_0 \) and \( \Delta = \gamma_1 \), where \( \alpha \) is the lattice constant given by \( a = 2.46 \, \text{Å}, \gamma_0 \approx 3 \, \text{eV} \), and \( \gamma_1 \approx 0.4 \, \text{eV} \). We shall completely neglect other interlayer couplings because they do not play important roles as has been discussed previously.

The states are specified by the set of quantum numbers \( j \) and \( k \), with \( k \) the wave vector and bands \( j = 1, 2, 3, 4 \) in the order of increasing energy (\( j = 1 \) and 2 for the valence bands and \( j = 3 \) and 4 for the conduction bands). The energy dispersion for varying values of the potential difference \( eFd \) is shown in Fig. 2.

We consider the situation that electron concentration \( n_e \) is varied by the bottom gate with a fixed value of the top-gate voltage giving external field \( F_{\text{ext}} \). The asymmetry between two layers causes difference in the electron density and then leads to that in the electrostatic potential. Therefore, \( eFd \) should be self-consistently determined for each electron concentration. Some examples of such calculations were carried out in ref. 37 for the static dielectric constant of the environment, \( \kappa = 2 \). We shall use this result for explicit calculations to be

Submitted to Journal of Physical Society of Japan
presented in the following.

2.2 Optical Absorption for Perpendicular Polarization

We apply external electric field $E_{\text{ext}}(\omega)e^{-i\omega t} + \text{c.c.}$ perpendicular to the layer, where ‘c.c.’ stands for complex conjugate. Let $n_1$ and $n_2$ be the electron density in layers 1 and 2, respectively, per unit area. The asymmetry in the density distribution $\Delta n(\omega)$ is defined as

$$\Delta n(\omega) = n_2(\omega) - n_1(\omega). \quad (2.4)$$

This induces electric field

$$(-e)E_{\text{ind}}(\omega) = -\frac{4\pi e^2 \Delta n(\omega)}{\kappa} \frac{\omega}{2}, \quad (2.5)$$
in the region $-d/2 < z < +d/2$, where $\kappa$ is the static dielectric constant of the environment. This is illustrated in Fig. 1 (b).

We shall define the polarizability $\alpha(\omega)$ through

$$(-e)^2 \frac{\Delta n(\omega)}{2} = \alpha(\omega) E_{\text{tot}}(\omega), \quad (2.6)$$

where $E_{\text{tot}}(\omega)e^{-i\omega t} + \text{c.c.}$ is the total electric field. Then, we have

$$(-e)E_{\text{tot}}(\omega) = (-e)E_{\text{ext}}(\omega) + (-e)E_{\text{ind}}(\omega)$$
$$= (-e)E_{\text{ext}}(\omega) - \frac{4\pi e^2 \Delta n(\omega)}{\kappa} \frac{\omega}{2}, \quad (2.7)$$
giving

$$E_{\text{tot}}(\omega) = \frac{E_{\text{ext}}(\omega)}{\varepsilon(\omega)} \frac{\omega}{\kappa} \alpha(\omega). \quad (2.8)$$

With the use of the equation of continuity, we have induced current

$$j(\omega) = -i\omega(-e)^2 \frac{\Delta n(\omega)}{2} = \frac{d}{d} \sigma_{zz}(\omega) E_{\text{tot}}(\omega), \quad (2.10)$$
in the region $-d/2 < z < +d/2$, with two-dimensional conductivity

$$\sigma_{zz}(\omega) = -i\omega\alpha(\omega) d. \quad (2.11)$$

Then, we have

$$\varepsilon(\omega) = 1 + \frac{4\pi}{\omega\kappa d} \sigma_{zz}(\omega), \quad (2.12)$$

and

$$j(\omega) = \frac{1}{d} \sigma_{zz}(\omega) E_{\text{ext}}(\omega), \quad (2.13)$$

with

$$\sigma_{zz}(\omega) = \frac{\sigma_{zz}(\omega)}{\varepsilon(\omega)}. \quad (2.14)$$

The power absorption per unit area is given by

$$P = \frac{d}{2} \text{Re} [j(\omega)E_{\text{tot}}(\omega)^*] = \frac{1}{2} \text{Re} \sigma_{zz}(\omega) |E_{\text{ext}}(\omega)|^2. \quad (2.15)$$

The dynamical conductivity can easily be calculated in a linear response theory. Define

$$\tilde{\sigma} = \begin{pmatrix} +1 & 0 & 0 \\ 0 & +1 & 0 \\ 0 & 0 & -1 \end{pmatrix}. \quad (2.16)$$

Then, we have

$$\sigma_{zz}(\omega) = i\omega e^2 d g_0 g_a \frac{1}{4} \sum_{a,b} \frac{(f_a - f_b) |\tilde{\tau}_{ab}|^2}{\varepsilon_a - \varepsilon_b + \hbar \omega + i\delta}, \quad (2.17)$$

where $\alpha$ and $\beta$ stand for a set of quantum numbers $(j, k)$, $g_a = 2$ and $g_\gamma = 2$ are the spin and valley degeneracy, $\delta$ is phenomenological broadening, and $f_\alpha = f(\varepsilon_\alpha)$ is the Fermi distribution function. We have used the fact that both K and K’ points give the same contribution. Explicitly, we have

$$\sigma_{zz}(\omega) = i\omega e^2 d g_0 g_a \frac{1}{4} \sum_{j,k} \int_0^\infty \gamma^2 k\,dk \,g_0(\gamma k)$$
$$\times \left[ f(\varepsilon_{jk}) - f(\varepsilon_{jk}') \right] |\tilde{\tau}_{jk}|^2. \quad (2.18)$$

In the above, we have introduced cutoff function,

$$g_0(\varepsilon) = \frac{\varepsilon_{n_c}^{n_c}}{\varepsilon_{n_c} + \varepsilon_{n_c}}, \quad (2.19)$$

with cutoff energy $\varepsilon_c \approx 3\,\gamma_0$ corresponding to the half of the $\pi$-band width and $n_c$ should be chosen in such a way that the integral should converge. The typical magnitude of the conductivity becomes

$$\sigma_0 = \frac{e^2 g_0 g_a}{4 \pi \gamma^2} \Delta^2 \approx \frac{e^2}{\pi \hbar} \frac{g_0 g_a}{4} \times 0.022, \quad (2.20)$$

where we have used $a = 2.46 \,\text{Å}, d = 3.34 \,\text{Å}, \Delta \approx 0.4 \,\text{eV}$, and $\gamma_0 \approx 3 \,\text{eV}$ in the last expression.

2.3 Symmetric Bilayer

In the symmetric case, in particular, we can make some analytic treatments. Let us define

$$\varepsilon(k) = \sqrt{\left(\frac{\Delta}{2}\right)^2 + (\gamma k)^2}, \quad (2.21)$$

$$\gamma k = \varepsilon(k) \sin \psi, \quad (2.21)$$

$$\Delta/2 = \varepsilon(k) \cos \psi,$$

where $\psi$ is 0 at $k = 0$ and approaches $\pi/2$ when $\gamma k \gg \Delta/2$. Then, the eigenenergies are given by

$$\varepsilon_{x1}(k) = 2\varepsilon(k) \sin^2(\psi/2), \quad (2.22)$$
$$\varepsilon_{x2}(k) = 2\varepsilon(k) \cos^2(\psi/2),$$

and the corresponding wave functions are given by

$$F_{xnk}(r) = \frac{1}{L} \exp(ik\cdot r) \mathcal{U} |\theta(k)| F_{xnk}, \quad (2.23)$$

where $L^2$ is the area of the system,

$$\mathcal{U}(\theta) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & e^{i\theta} & 0 & 0 \\ 0 & 0 & e^{i\theta} & 0 \\ 0 & 0 & 0 & e^{2i\theta} \end{pmatrix}. \quad (2.24)$$
and
\[ F_{1k} = \frac{1}{\sqrt{2}} \begin{pmatrix} s \cos(\psi/2) \\ \sin(\psi/2) \\ -s \sin(\psi/2) \\ -\cos(\psi/2) \end{pmatrix}, \quad (2.25) \]
\[ F_{2k} = \frac{1}{\sqrt{2}} \begin{pmatrix} s \sin(\psi/2) \\ \cos(\psi/2) \\ s \cos(\psi/2) \\ \sin(\psi/2) \end{pmatrix}, \quad (2.26) \]

We have the correspondence shown in Table I between quantum number \( j \) and \((s,n)\) with \( s=\pm \) and \( n=1,2 \). The matrix elements of \( \tilde{\tau} \) are calculated as in Table II.

Consider the case that the Fermi level lies in the band \( j=3 \) or \((+1)\). For the transition \((+1)\to(+2)\), in particular, we have
\[ \epsilon_{+2}(k)-\epsilon_{+1}(k) = \Delta, \quad (2.27) \]

independent of \( k \). Further, we have
\[ (+,2)\tilde{\tau}(+,1) = \sin \psi. \quad (2.28) \]

Define \( n_\psi^0 \) be the electron concentration when the Fermi level reaches the bottom of band \((+,2)\) or \( \epsilon_F = \Delta \), i.e.,
\[ n_\psi^0 = \frac{g_v g_\theta}{2\pi \gamma^2} \Delta^2. \quad (2.29) \]

Then, the transition strength averaged over states up to the Fermi energy becomes
\[ \langle \sin^2 \psi \rangle = 1 - \frac{1}{8} n_\psi^0 n_\psi^0 \ln \left( 1 + \frac{n_\psi^0}{n_\psi^0} \right), \quad (2.30) \]

where \( \langle \cdot \cdot \cdot \rangle \) means the average over states with energy lying between \( \epsilon = 0 \) and \( \epsilon_F \). Then, we have
\[ \sigma_{zz}(\omega) = \sigma_0 \frac{\hbar \omega n_\psi}{\Delta} \frac{(-2i)\langle \sin^2 \psi \rangle \Delta^2}{\Delta} \frac{\Delta}{(\hbar \omega + i\delta)^2}, \quad (2.31) \]

with
\[ \beta = 8\pi g_v g_\theta e^2 \frac{d^2}{\kappa^2} \Delta^2 \frac{\langle \sin^2 \psi \rangle n_\psi}{n_\psi^0}. \quad (2.32) \]

This shows that the resonance energy is shifted from \( \Delta \) to \( \sqrt{\Delta^2+\beta} \Delta \) due to the depolarization effect. For \( n_\psi/n_\psi^0 = 1 \), in particular, we have \( \langle \sin^2 \psi \rangle = 0.725 \ldots \) and \( \beta = 0.68 \ldots \), giving about 30% shift of the resonance energy to the higher energy side.

For the transition \((-1)\to(+1)\), we have \( |-1|\rho_+ = 1 \) and
\[ \epsilon_{+1}(k)-\epsilon_{-1}(k) \approx \frac{\hbar^2 k^2}{m^*}, \quad (2.33) \]

with
\[ \Delta \quad (2.34) \]

Then, we have
\[ \sigma_{zz}(\omega) \approx \sigma_0 \frac{\hbar \omega}{4\Delta} \left[ \pi \theta \left( \frac{\hbar \omega}{2} - \frac{\gamma^2 h^2}{\Delta^2} \right) \right] \]
\[ -i \ln \left| \frac{4\epsilon_\psi^2/\Delta^2}{(\gamma^2 h^2/\Delta^2) - (\hbar \omega)^2} \right|, \quad (2.35) \]

This shows that the absorption exhibits a step-function-like behavior with a spectral edge suppressed by the logarithmic divergence of \( \epsilon(\omega) \).

For the transition \((-2)\to(+2)\), we have
\[ \epsilon_{+2}(k)-\epsilon_{-2}(k) \approx 2\Delta + \frac{\hbar^2 k^2}{m^*}. \quad (2.36) \]

Then, we have
\[ \sigma_{zz}(\omega) \approx \sigma_0 \left( \frac{\pi \theta}{2} \left[ (\hbar \omega)^2 - (2\Delta)^2 \right] - \frac{i}{2} \ln \left( \frac{2\Delta + \hbar \omega}{2\Delta - \hbar \omega} \right) \right), \quad (2.37) \]

showing that the absorption exhibits a step-function-like behavior with a suppressed edge.

Transitions \((-1)\to(+2)\) and \((-2)\to(+1)\) are both forbidden in a symmetric bilayer. When slight asymmetry in the potential is introduced, however, bands \((-1)\) and \((+1)\) start to be mixed with each other. The effective Hamiltonian becomes
\[ (+1) \quad (2.38) \]

\[ H_{eff} = \left( \begin{array}{cc} +2\epsilon(\sin^2(\psi/2) & -(eF/2) \cos \psi \\ -(eF/2) \cos \psi & -2\epsilon(\sin^2(\psi/2) \end{array} \right). \]

Thus, for \( k = 0 \), two states are mixed with equal amplitude. As a result, the transitions from \((-1)\) to \((+,2)\) and from \((-2)\) to \((+,1)\) become allowed in the vicinity of \( k = 0 \) and a small absorption appears near \( \hbar \omega \approx \Delta + |eF| \) for nonzero \( F \) (see §4).

2.4 Optical Absorption for Parallel Polarization

The dynamical conductivity describing optical absorption for electric field parallel to the layer was calculated previously \((\text{30})\) and therefore we shall give only the final results. The dynamical conductivity becomes
\[ \sigma_{xx}(\omega) = g_v g_\theta \left( \frac{\epsilon_\psi}{\hbar} \right)^2 \frac{\hbar}{\Delta} \sum_{\alpha,\beta} \left| \frac{\langle \alpha | \Sigma_x | \beta \rangle}{(\epsilon_\alpha - \epsilon_\beta)(\epsilon_\alpha - \epsilon_\beta + \hbar \omega + i\delta)} \right|^2, \quad (2.39) \]

with
\[ \Sigma_x = \left( \begin{array}{ccc} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{array} \right). \quad (2.40) \]

This can be separated into the Drude (intra-band) part and the inter-band part
\[ \sigma_{xx}(\omega) = g_v g_\theta \left( \frac{\epsilon_\psi}{\hbar} \right)^2 \frac{\hbar}{\Delta} \left[ \sum_{jk} \frac{\partial f(\epsilon_{jk})}{\partial \epsilon_{jk}} \frac{|\langle j | \Sigma_x | k \rangle|^2}{(\hbar \omega + i\delta)} \right. \]
\[ - \left. \sum_{j \neq j', k} \frac{|\langle j | \Sigma_x | j' \rangle|^2}{(\epsilon_{jk} - \epsilon_{j'k})(\epsilon_{jk} - \epsilon_{j'k} - (\hbar \omega + i\delta))^2} \right], \quad (2.41) \]

The squared matrix element for a symmetric bilayer is listed in Table III. At the band edges \( k = 0 \) or \( \psi = 0 \), the selection rule for the parallel and perpendicular polarized light is completely different. The dynamical conductivity for \( \epsilon_F = 0 \) has essentially no prominent structure except a step-like increase corresponding to transitions from \((-1)\) to \((+,2)\). \((\text{30})\) With increase in \( \epsilon_\psi \), a delta-function
conductivity describing optical properties has symmetry ing electron concentration as has been estimated in the previous section. the solid lines ̃σ_{zz}(ω) with depolarization effect. We assume broadening parameter δ/Δ = 0.02. One most prominent feature is the appearance of a sharp peak corresponding to transitions from (+, 1) to (+, 2) with the increase of ε_F. In the clean limit δ → 0, the peak becomes a δ function because the bands are parallel to each other. For perpendicular polarization, this sharp peak is shifted to the higher energy side due to the depolarization effect. When the Fermi level reaches the bottom of band (+, 2), this shift is as large as 30 % as has been estimated in the previous section.

Figure 4 shows the dynamical conductivity for varying electron concentration n_s for F_{ext} = 0, i.e., when the bilayer is symmetric for n_s = 0 and the asymmetry potential ε_Fd increases with the change of n_s. The energies where interband transitions start to appear are shown by thin dotted lines. For transitions from (+, 1) to (+, 2), i.e., 3 → 4, the upper edge where the transition disappears is also included.

For the parallel polarization, the absorption corresponding to transitions (+, 1) → (+, 2) becomes broadened with increase of n_s due to the gap opening. For the perpendicular polarization, on the other hand, this broadening is not significant and exhibits a similar amount of shift due to the depolarization effect. This is because the resonance, i.e., the zero point of ε(ω), occurs at an energy higher than the interband continuum due to the depolarization effect. A weak structure appears near the line denoted as 2 → 4 with the increase of n_s. This corresponds to the transition from (−, 1) to (+, 2), which becomes allowed by the band-gap opening as mentioned in the end of the last section.

Similar results for ε_{Fdc}/Δ = 1 are shown in Fig. 5. For the parallel polarization, the absorption corresponding to transitions (+, 1) → (+, 2) is considerably broadened due to further increase of the gap with n_s. The absorption for the perpendicular polarization tends to have a sharper peak near the higher-energy edge of the interband continuum and exhibits a sharp peak for sufficiently large n_s where the zero of ε(ω) is well separated from the continuum. The transition from (−, 1) to (+, 2) denoted as 2 → 4 is now much more prominent. The peak appearing at ̃σ_{zz}(ω) for the parallel polarization is due to the opening of gap ∼ ε_{Fdc}.

Figure 6 shows results for ε_{Fdc}/Δ = −1 corresponding to asymmetry opposite to Fig. 5. In this case the asymmetry becomes weaker with n_s and therefore the peak corresponding to transitions (+, 1) → (+, 2) becomes sharper with n_s. Further, the transition from (−, 1) to (+, 2) denoted as 2 → 4 for the perpendicular polarization becomes weaker with the increase of n_s.

§4. Discussion and Summary

We have calculated the optical absorption spectrum for light with electric field perpendicular to bilayer graphene and shown that the spectrum is quite different from that for the parallel polarization. This arises partly from the difference in the selection rule and from the important depolarization effect due to induced charge imbalance between two layers. The depolarization effect is most prominent for the sharp transition (+, 1) → (+, 2) almost parallel to each other.

The strength of the absorption for the perpendicular polarization is determined by conductivity ̃σ_{zz}(ω) of the order of σ_0, while that for the parallel polarization by σ_{xx}(ω) of the order of (g_F g_L e^2)/(4πh). Because σ_0 ∼ 0.022 × (g_F g_L e^2)/(4πh), the absorption intensity for perpendicular polarization is much smaller. As a result, for light incident with certain angle from the vertical direction the absorption by the field component perpendicular to the layer is small and usually negligible.

This smallness of ̃σ_{zz}(ω) mainly comes from the fact that inter-layer coupling γ_1 (~ 0.4 eV) is much smaller than intra-layer coupling γ_0 (~ 3 eV) in spite of the fact that inter-layer separation d (= 3.34 Å) is not so much different from the intralayer lattice constant a (= 2.46 Å). This is quite in contrast to conventional space-charge layers on semiconductor surfaces where ̃σ_{zz}(ω) is not so much different from σ_{xx}(ω). Usually, ̃σ_{zz}(ω) can be experimentally measured using the configuration of a transmission line. The weak absorption intensity discussed above requires the use of bilayer graphene with large area.
